Context

Aerodynamics is a key factor in improving cycling performance and the measurement of the drag force is therefore of the utmost importance. Among all the existing methods, the wind tunnel remains the reference thanks to its reliability. However this approach is not an option for most cyclists due to its cost and lack of availability. Such technique is also extremely time consuming and its integration into an iterative bike adjustment process is hard to implement in practice.

In this context, previous works have shown that 3D scan coupled with computational fluid dynamics (CFD) can successfully approximate the wind tunnel measurements at a lower cost [1,2]. Following this idea, we have developed a new computer vision-based method to estimate the aerodynamic drag of cyclists [3]. First a 3D model of the cyclist is built by a system that captures the motion and the morphology of a parametric body model using 4 RGB-D cameras; subsequently, a CFD solver processes this model to estimate the aerodynamic resistive forces. In another work we also showed a good experimental agreement between our 3D+CFD technique and wind tunnel [4]. Our system can therefore be an affordable alternative to wind tunnel measurements. This promising solution makes it possible to quickly build a

45 synthetic 3D+t model of a cyclist with a
46 relatively light device but the CFD
47 computing remains nevertheless quite
48 time consuming.

In this study, following the idea developed in [5], we propose to design a learning-based system that approximates CFD simulations for the specific case of a cyclist on his bike. In our approach, the 3D shape for which the drag force is calculated is entirely defined by the morphology and the posture of the rider plus the dimensions of the bike. This set of parameters and the wind speed should therefore be sufficient to predict the drag force.

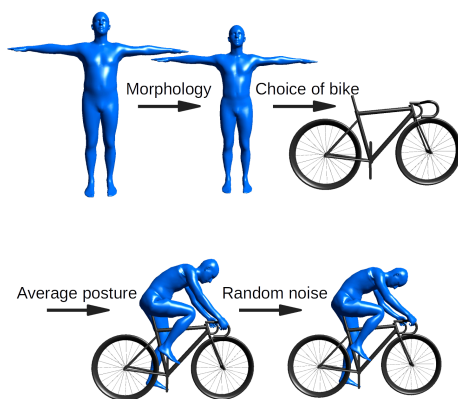

Method

We trained a neural network with parametric models identical to those produced by our 3D scanning device. The drag force computed by the CFD software was used as ground truth. Several thousands of data are required to train the neural network and, as we did not have enough real data, we built a

76 synthetic data set from randomly chosen
77 parameters.

79 Dataset

80 For each sample, a gender and the
81 morphological parameters are first
82 randomly drawn. The bike frame is
83 chosen according to the resulting body
84 size. The saddle height, handle bar height
85 and the stem are randomly altered
86 around the nominal values. The body
87 model is placed on the bike for a random
88 hand pose and crank angle. Finally, the
89 head flexion, spine flexion, elbow flexion
90 and shoulder torsion are randomly
91 modified. Then, the input/output training
92 pair is created by computing the drag
93 force for a randomly chosen wind speed
94 and direction.

95 *Steps to create a cyclist model*

96 More than 100,000 simulations were
97 collected from 11000 different
98 morphologies and postures coupled with
99 several wind directions and speeds
100 ranging from 20 to 60 km/h. Note that
101 about 1/3 of the data corresponds to a
102 headwind because this specific case is the
103 main use case.

107 Dimension reduction

108 The full body model is described by
109 75 posture and 10 morphology
110 parameters. 50 additional parameters are
111 required for the bike. To avoid over
112 fitting, we need to drastically reduce
113 input space of the neural network. To do
114 this while minimizing the loss of

115 information as much as possible, we
116 have kept only the following parameters:
117 gender, the 4 most statistically significant
118 morphological parameters, saddle
119 height, crank angle, handle bar height,
120 horizontal distance between bottom
121 bracket and handle bar, hand pose (top,
122 brake, or down), average left and right
123 shoulder torsion, average left and right
124 elbow flexion, head and back flexion. By
125 adding wind speed and direction, only
126 16 input parameters are thus retained in
127 total.

129 Learning

130 4 different multilayer perceptrons
131 (MLP) with 1, 2, 5 and 8 hidden layers
132 were tested. The architecture with 5
133 hidden layers provided the best results,
134 with 25, 10, 10, 6 and 5 neurons in the
135 successive hidden layers. The
136 LeakyReLU activation function was used
137 between all hidden layers, and a linear
138 activation function is applied in the
139 output layer. LeakyReLU has the
140 advantage of solving the problem of
141 vanishing gradient which becomes
142 particularly useful in deeper neural
143 networks.

145 Results

146 25% of the data has not been used
147 for learning and kept for validation. On
148 this dataset, the root mean square
149 difference (RMSE) between the estimated
150 drag force and the CFD is 0,95 Newton.
151 This first evaluation is encouraging but
152 cannot be the considered as an indicator
153 of the expected error on real data,
154 because the synthetic data does not
155 include all the small variations seen in
156 the real world.

157 To assess the approach more
158 realistically, we compared the drag force
159 estimated from the complete chain 3D
160 scan/machine learning against the drag
161 force measured in a wind tunnel. The
162 graph below shows all data pair for
163 multiple cyclists, postures and wind
164 speeds; the RMSE is about 1,2 Newton.

168
169 **Conclusion**

170 In this work we presented a
171 machine learning-based technique to
172 quickly approximate the results of a
173 time-consuming CFD simulation of a
174 cyclist riding on his bike. The key idea is
175 to use a parametric description of the
176 cyclist shape as input to a neural
177 network.

178 The results are very encouraging
179 (RMSE of 1,2 Newton against wind
180 tunnel measurements) but for now only
181 variations having an impact on the input
182 parameters can be observed. This
183 excludes the shape of the helmet or the

184 diameter of the frame tubes for example.
185 However, this technique could
186 advantageously replace the CFD part of
187 our drag force measurement system.
